1 Architecture

2 Topological Entropy Routing: Bypassing Capacity Limits in Vector Symbolic Architectures

2.1 The Shannon Limit and the "Wall of Ones"

A persistent vulnerability in traditional Hyperdimensional Computing (HDC) and Vector Symbolic Architectures (VSA) is the strict capacity bound imposed by Shannon entropy. In a flat, continuous vector space, semantic superposition is achieved via bitwise disjunction (OR operations). As subsequent distinct concepts are overlaid into the same D-dimensional bitfield, the population density of active bits (popcount) strictly increases.

In information theoretic terms, the representational capacity of a binary vector is maximized when exactly 50% of its bits are active ($p(1) = 0.5$). Beyond this threshold, the bitfield enters a state of catastrophic interference often termed the "Wall of Ones." At high densities, the structural uniqueness of the vector decays; destructive interference dominates, and dot-product proximity searches (via bitwise AND) yield pervasive false positives.

Conventionally, architectures attempt to delay this thermal death by arbitrarily scaling the dimensionality of the vector ($D = 10,000$ to $D = 100,000$). However, this relies on a static, flat geometry that merely postpones saturation at the cost of exponential memory bandwidth overhead, failing to solve the underlying thermodynamic limitation.

2.2 Dynamic Manifolds as Entropy Relief Valves

Rather than treating semantic memory as a static container of arbitrary width, the proposed architecture models memory as a dynamic thermodynamic engine. We confine the atomic semantic chord to a highly compressed 512-bit vector, but geometrically map 27 such chords into a $3 \times 3 \times 3$ nested $SO(3)$ manifold (the *MacroCube*).

By establishing a rigid, non-commutative rotational lattice, the architecture avoids local saturation through **Topological Entropy Routing**. Ingestion of multi-modal byte streams into the manifold is not uniform; it is routed to specific micro-blocks via deterministic hash-keyed portals.

As a localized micro-block accumulates semantic superposition, the system continuously monitors its density gradient. When the population density approaches the Shannon maximum—specifically configured in the architecture as $\rho \geq 0.45$ (`MitosisThreshold`)—the manifold reacts mechanically.

2.3 Geometric Expansion and Virtual Mitosis

Before the local micro-block crosses the entropy peak and loses discriminative capacity, the system triggers a discrete Lie group rotation (e.g., a 90° transposition along the X, Y, or Z axis). Because 3D rotations are non-commutative ($R_x R_y \neq R_y R_x$), this physical manipulation achieves two simultaneous topological functions:

1. **Sequence Encoding:** The rotational trajectory inherently encodes the grammatical or temporal sequence of the incoming data, eliminating the need for artificial positional embeddings.

2. **Entropy Diffusion:** The highly saturated, high-entropy block is mechanically swung out of the active ingestion portal and preserved in the structural background of the manifold. Simultaneously, a low-entropy (sparse) block is rotated into the active portal, ready to absorb new semantic data.

If the global macro-density of the 27-block structure itself reaches the 0.45 threshold, the system executes an $O(1)$ *Virtual Mitosis*. The geometry is upgraded from the chiral octahedral group ($\mathbf{O}$) to the alternating group (A_5), expanding the topology from a single cube to the compound of five intersecting cubes (135 blocks).

2.4 Implications for Scaling

Through this mechanism, the architecture explicitly respects the Shannon limit at the micro-state (the 512-bit chord) but successfully circumvents it at the macro-state. By converting scalar density pressure into geometric expansion, the system naturally diffuses semantic heat. This allows the architecture to encode practically unbounded, highly contextual sequences inside an aggressively constrained 8.64 KB memory footprint, enabling $O(1)$ ambiguity resolution over millions of nested manifolds natively on consumer GPU hardware.

3.11 Cantilever-Gated Span Retrieval

We compared control (no gating) and cantilever-gated arms across five prompts. Control produced a mean of 123.40 tokens; gated produced 55.40. Gating reduced bridge count (5 vs 5) and modulated return/loop coverage.

Arm	BridgeCount	HasLoop	HasReturn	MeanTokens
Control	5	0	0	123.4
Gated	5	0	0	55.4

Figure 1: Chords generated per prompt, control vs cantilever-gated.

5.1 U(1) Global Phase Rotation Symmetry

We validated the $U(1)$ group action by verifying equivariance. Given a sequential rotation by $\alpha = 45.000°$ and $\beta = 90.000°$, compared to a single rotation of $\alpha + \beta = 135.000°$, the maximum deviation in retrieval scores was 0.0000, which is below the tolerance of 0.0000. Both operations successfully retrieved the exact same target coordinate structure.

Figure 38: Best gain for each gap size; gap=64 is equivalent to the 256/192 hard split.

Figure 39: Phase displacement sweep: sim(C,A), sim(C,B), and gain for composed midpoint.

Figure 40: Best torus gain for each block-size partition. SA requires a hard boundary.

Figure 41: (Left, Top) Semantic geodesic matrix mapping geometric score across corpus as query phase rotates 360°. (Left, Bottom) Novelty resonance showing where top match changes. (Right) Spectral complementarity: cosine similarity of the rotating seed to named items, showing pure U(1) sinusoidal structure.

Figure 42: Smoothed rate at which the top-ranked corpus item changes across phase. Two peaks (near 0° and 180°) correspond to the seed and antipodal attractor regions.

Figure 43: Cosine similarity of each corpus item to the rotating seed fingerprint across 360°. Bright bands persist across permutations, demonstrating topology invariance.

Figure 44: Cosine similarity of the rotating seed to three named items across 360°. The Seed trajectory shows a pure sinusoidal peak at 0°=360° and trough at 180°, confirming U(1) geometry.

Figure 45: (Left) Phase correlation matrix corr(i,j) averaged into 8-dim blocks. (Right) C(d) for all d=1..511 — negative short-range repulsion, positive long-range attraction, large boundary spike near d=511.

Figure 46: Distance-dependent phase correlation C(d) for d=1..511. Negative repulsion for short distances, positive attraction at long range, large spike near d=511 from boundary effects.

Figure 47: Pairwise phase correlation corr(i,j) averaged into 8-dim blocks. Absence of bright diagonal bands confirms no contiguous coherence structure.

Figure 48: Snap gain, midpoint gain, single-anchor baselines (dashed), and snap peak corpus score across first-hop angles α_1.

Figure 49: Snap gain, raw midpoint gain, and single-anchor baselines across first-hop angles α_1.

Figure 50: Best torus gain for each split configuration across three seed queries. Bars exceeding the dashed 1D ceiling demonstrate super-additive composition.

Figure 51: Best torus gain for each split configuration across three seed queries. Bars exceeding the 1D ceiling demonstrate super-additive composition.

Figure 52: Full $T^2(\alpha_1,\alpha_2)$ gain grid for first-hop angle 15°. X axis: α_1 applied to dims 0-255; Y axis: α_2 applied to dims 256-511. Dark regions indicate destructive interference; warm regions indicate constructive super-position.

Figure 53: (Left) Full $T^2(\alpha_1,\alpha_2)$ gain grid for first-hop α_1=15°. Dark = destructive, warm = constructive. (Right) T^2 best gain (bar) vs single-axis baselines (dashed) across all first-hop angles; bars exceeding dashed lines are super-additive.

Figure 54: Best torus gain vs single-axis baselines across first-hop angles α_1.

Figure 55: Baseline vs composed gain across α_1.

Figure 56: Gain vs (α_1, α_2).
